The type 2 diabetes epidemic currently faced by increasing numbers of countries has led to many investigations that analyze the negative effects of glucose on the health, function and fate of cells, tissues, organs and body systems. This is certainly true for skeletal health, as patients suffering from type 2 diabetes mellitus have increased fracture risk, despite normal-to-high bone mineral density.1-4 There is no doubt that long-term hyperglycemia adversely affects bone; yet, a recent paper by Wei et al.5 published in Cell highlights the importance of glucose for functional health and perhaps even commitment of mesenchymal cells to the osteoblast lineage and bone formation.

Glucose is a major source of energy for active bone-forming osteoblasts. Interestingly, Wei et al. have demonstrated that, in the mouse, the uptake of glucose into osteoblasts accounts for a large proportion of total body glucose uptake, being one-fifth of that taken up by skeletal muscle and half of what is taken up by white adipose tissue. Second, they show that osteoblastic glucose uptake is insulin independent and, finally, that glucose uptake is likely to be responsible for the commitment of osteoprogenitors and bone development.5 The mRNA level of Glut1 was almost 100 times higher than that of other glucose transporters in osteoblasts.6 The authors characterized the role of GLUT1 in skeletal development and bone formation through a series of genetic knockouts in mice.

Commitment of osteoprogenitor cells is the first stage in osteoblast formation and development. The condensation of mesenchymal cells during embryonic development is followed by rapid differentiation of these cells into their lineages, including chondroblasts and osteoblasts, for skeletal development.6 This process is tightly controlled so that mesenchymal cells differentiate into chondroblasts or pre-osteoblasts, and then into mature osteoblasts, which in turn increase bone matrix deposition and mineralization. The particular progression of mesenchymal cells into osteoblasts is known as osteoblastogenesis. Osteoblastogenesis is tightly regulated by a choreographed expression pattern of particular transcription factors.

Runt-related transcription factor 2 (RUNX2), also known as core-binding factor subunit alpha-1, is encoded by the Runx2 gene. RUNX2 has been identified as the major transcription factor in the control of osteoblastogenesis and osteoblast function during both endochondral and intramembranous ossification.7-8 Similar to other members of the RUNX family of transcription factors, RUNX2 contains a Runt DNA-binding domain that can bind DNA either alone or as a complex with other transcription factors. The early commitment of mesenchymal stem cells into osteoblasts requires the expression of Runx2 that regulates the expression of several important bone proteins, including type 1 collagen, bone sialoprotein, osteopontin, transforming growth factor β, alkaline phosphatase (ALP) and osteocalcin (OCN), among others. Runx2 displays haploinsufficiency in humans where patients with a mutation in one allele are affected with a skeletal condition known as cleidocranial dysplasia characterized by suppressed bone formation.9 It has become clear that certain transcription factors lead to Runx2 expression at different time points during the commitment process of mesenchymal cells to the osteoblast lineage, including Hoxa2, a member of the Hox homeodomain family of transcription factors, SABT2,10 and even the suppression of chondroblastogenic factors including Sox911 and certain microRNAs that act as inhibitors of bone formation.12 The exact chronology and identification of all the required factors for expression of Runx2 are still unclear.

Type I collagen is synthesized by osteoblasts and is the most abundant organic component of the extracellular bone matrix (ECM). It consists of two α1 and one α2 chains, encoded by separate genes. The promoter region of the most highly expressed α1 chain has a specific RUNX2-binding domain, leading to the supposition that the initial expression of type I collagen was driven by RUNX2. However, Wei et al. use in situ hybridization to show that, in vivo, type I collagen synthesis occurs in developing hind limbs before the expression of Runx2. This indicates that there is another trigger for the movement of mesenchymal cells into the osteoblast lineage. Examination of the Glut1 transporters in these same developing limbs identified that these transporters were also expressed before Runx2. GLUT1 is an insulin-independent glucose (and Vitamin C) transporter, encoded by the gene: SLC2A1 (or Glut1).13 GLUT 1 is known to facilitate basal glucose uptake in the brain and
eurythrocytes, for example.\textsuperscript{14} Other studies have also shown an important role for GLUT1 in insulin-independent glucose metabolism in osteoblasts.\textsuperscript{15}

Induction of Glut1 knockout in both early and later embryonic development verified the importance of these glucose transporters in osteoblastogenesis and bone formation.\textsuperscript{5} Both models resulted in reduced ECM mineralization, decreased osteoblast differentiation, reduced trabecular thickness and delayed OCN expression. Interestingly, Runx2 and type I collagen expression were normal in the osteoblast-specific Glut1-knockout mice; yet, accumulation of RUNX2 and collagen I protein was decreased. Induction of Glut1 transporter knockout either at the postnatal or at the 6-week stage resulted in mice with low bone mass, reduced osteoblast proliferation, reduced OCN expression, and reduced glucose and insulin tolerance at 3 months of age. As these effects are a consequence of knocking out the most abundant glucose transporter in osteoblasts, the authors conclude that they are likely due to an overall reduction in energy supply, leading to a reduction in total protein synthesis.

Mammalian target of rapamycin complex 1, or mTORc1, is a nutrient-sensitive kinase complex that regulates, in particular, nucleotide and protein synthesis, and thus orchestrates cell growth and proliferation. mTORc1 and AMPK are reciprocally regulated via nutrient availability.\textsuperscript{16} Considering the effect of reduced glucose uptake in the Glut1-knockout mice, Wei et al.\textsuperscript{5} analyzed the effect of the knockout on mTORc1 and confirmed its involvement via increased AMPK activity (see Figure 1). Further, in an elegant mouse model in which AMPK activity was reduced by deletion of one AMPK subunit allele in the Glut1 osteoblast knockout model, they observed restored ATP levels, as well as restored RUNX2 and type I collagen protein accumulation.

The observed normal Runx2 expression alongside low levels of RUNX2 protein accumulation in Glut1-null osteoblasts led the authors to consider whether the lack of Glut1 and the reduced glucose uptake in these cells led to increased RUNX2 ubiquitination and thus increased proteasomal degradation. Indeed, the ubiquitin ligase, SMURF1, was shown to trigger this degradation via AMPK activity (see Figure 1).\textsuperscript{17} To assess the role of glucose uptake in RUNX2-mediated transcription of Glut1 itself and osteoblast differentiation markers, including osteocalcin, AMPK activity also decreases mTORc1 activation. Glucose uptake via Glut1 therefore also promotes mTORc1 activity, which leads to collagen synthesis and bone formation. Ub, ubiquitin; $\text{PO}_4^-$, phosphate.

![Figure 1](image-url)  
**Figure 1** Mechanisms leading to glucose-induced osteoblast differentiation and bone formation. Glucose uptake via insulin-independent GLUT1 transporters in the preosteoblast inhibits the phosphorylation of AMPK. Phosphorylation of AMPK activates the ubiquitin ligase, Smurf1, which in turn targets RUNX2 for proteasomal degradation. Thus, glucose uptake via GLUT1 promotes RUNX2-mediated transcription of Glut1 itself and osteoblast differentiation markers, including osteocalcin. AMPK activity also decreases mTORc1 activation. Glucose uptake via GLUT1 therefore also promotes mTORc1 activity, which leads to collagen synthesis bone and formation. Ub, ubiquitin; $\text{PO}_4^-$, phosphate.
promoter region and increases the activity of the promoter. Runx2 expression is correlated with Glut1 expression, likely explaining the low-glucose uptake and undetectable mTORc1 signaling in osteoblasts lacking Runx2. These data imply that there is a feedforward loop that regulates the uptake of glucose by Glut1 transporters and the functions of the master osteoblast transcription factor RUNX2 (see Figure 1). Indeed, skeletal preparations of heterozygote Runx2-knockout mice crossed with mice lacking one allele of osteoblast-specific Glut1 mimic Runx2−/− mice at E16.5, and continue with problematic skeletal formation and mineralization beyond that time point. These malformations were improved in the embryos of hyperglycemic mothers.

Altogether, this comprehensive study relates the energy requirements of early pre-osteoblastic stem cells to their fate. These cells require glucose uptake, via insulin-independent GLUT1 facilitation, to trigger the stable expression and accumulation of the major transcription factors involved in osteoblastogenesis and proteins involved in bone formation. GLUT3 transporters have also been identified in bone and may have a role in insulin-dependent glucose transport in the developing skeleton. Importantly, however, the data presented in the study by Wei et al. indicate that it is glucose uptake in these cells that drives the expression of type I collagen before RUNX2 expression and accumulation. Although the study showed that RUNX2 is clearly necessary for osteoblast differentiation and function, the most notable result of this investigation was that increased glucose exposure in osteoblasts lacking Runx2, but not increased RUNX2 accumulation in osteoblasts lacking Glut1, improved collagen expression. Future studies, including in humans, are necessary to conclude whether nutritional-based treatments in patients with skeletal dysplasia might be useful and careful consideration of the negative effects of high-glucose and high-fat diets on the skeleton is required.

Conflict of Interest

The authors declare no conflict of interest.
